

Eczema, Dermatitis, and Itchy Red Skin Marks - Educational Guide

Compiled for Medically RAG demo from common public-health educational themes (educational use only; not clinical advice).

Overview

Itchy red marks on the skin are common and have many possible causes. Frequent explanations include eczema (atopic dermatitis), contact dermatitis, urticaria (hives), fungal infections, insect bites, and allergic reactions. This guide summarizes educational information for retrieval-augmented assistants and is not a diagnosis.

Eczema (Atopic Dermatitis)

Eczema often causes dry, itchy, inflamed skin that may look red or darker than surrounding skin depending on complexion. Scratching can worsen irritation and lead to thickened skin or secondary infection. Triggers may include soaps, fragrances, sweat, allergens, stress, and climate changes. Supportive care usually emphasizes gentle cleansing, frequent moisturizing, avoiding known irritants, and seeking medical care for severe, spreading, or infected rashes.

Contact Dermatitis

Contact dermatitis appears after the skin touches an irritant or allergen such as nickel, poison ivy, latex, cosmetics, or cleaning chemicals. The rash is often localized to the exposure area and may burn, itch, or blister. Identifying and removing the trigger is central. Persistent or severe reactions warrant clinician evaluation.

Urticaria (Hives) and Allergy Clues

Hives are raised, itchy welts that can appear suddenly and migrate. They may follow foods, medicines, infections, or unknown triggers. Immediate medical attention is needed for swelling of lips/tongue/throat, breathing difficulty, dizziness, or fainting, which can signal anaphylaxis.

When to Seek Care

Seek urgent care for rapidly spreading rash with fever, pain, pus, blistering over large areas, facial/oral swelling, or breathing problems. For chronic itch with red marks, a clinician can help distinguish eczema from infection, psoriasis, scabies, or other conditions.
